Short Summary

This paper offers theoretical insights into deep learning's generalization ability, addressing the "apparent paradox" of its success despite high capacity and complexity.

Here are the most important concepts:

- * **Rethinking Generalization:** Challenges the traditional view that small capacity, stability, robustness, or flat minima are *necessary* for generalization in specific deep learning instances, proposing that these factors are often sufficient but not universally required.
- * **Open Problem 2:** Introduces a new open problem to characterize generalization purely based on the hypothesis, true distribution, and given dataset, moving beyond properties of the entire hypothesis space or algorithm.
- * **Validation-Based Guarantees:** Demonstrates that validation datasets can provide non-vacuous and numerically tight generalization guarantees for deep learning, regardless of model capacity or complexity.
- * **Direct Neural Network Analysis:** Provides a direct analysis for neural networks, showing that generalization hinges on factors like "path weights" and the concentration of data in the learned feature representation space, rather than simply the number of parameters or network depth.
- * **Two-Phase Training:** Proposes and empirically evaluates a novel two-phase training procedure that explicitly breaks the dependence of feature representations on the full training dataset, aiding theoretical analysis of generalization.
